ABSTRACT

The Coronavirus disease 2019, identified by Chinese researchers to be the caused by a novel enveloped betacoronavirus, Severe Acute Respiratory Syndrome Coronavirus- 2 which was first isolated in Wuhan, China has been declared a global pandemic by the world health organization. The virus has several structural proteins that contributed to its pathogenesis such as spikes, membrane, envelop and nucleocapsid protein facilitating its attachment, entry and cell-to-cell transmission. The virus is readily transmitted through human-to-human contact and there is presently no approved vaccine for its prevention. This study was carried out to review the epidemiology of Severe Acute Respiratory Syndrome Coronavirus- 2, its host and reservoir, pathogenesis, transmission, clinical manifestation and potential treatment options for the infection.

Introduction

Coronaviruses are enveloped single stranded positive sense RNA viruses that are zoonotic in nature (1). The coronaviruses genome is said to be the largest known RNA virus genome with a genome size approximately 26-32 kilobases (2).

The coronavirus belongs to the order Nidovirales under the family coronaviridae. The coronavirinae which is one of the subfamilies of the coronaviridae family is further subdivided into four groups; the Alpha, Beta, Gamma and Delta coronaviruses. All coronaviruses have 16 non-structural proteins (nsp1–nsp16) and 4 structural proteins (3) except the betacoronaviruses with 5 structural proteins (4). The four main structural proteins are spike (S), membrane (M), envelope (E), and nucleocapsid (N) proteins (3, 5).

The coronavirus disease 2019 (COVID-19) has been identified to be caused by a novel enveloped RNA betacoronavirus belonging to the orthocoronavirinae subfamily (6, 7). As a result of the phylogenetic similarity between the causal pathogen of COVID-19 and SARS-CoV, the novel virus is currently called Severe Acute Respiratory Syndrome Coronavirus- 2(SARS-CoV-2). This SARS-CoV-2 is a strain of severe acute respiratory syndrome-related coronavirus (SARSr-CoV) (8). The virus genome consists of six open reading frames (ORFs) that are common to coronaviruses and its genes shared more than 80% nucleotide sequence identity to SARS-CoV. The disease presents with complications such as severe pneumonia, respiratory failure, acute respiratory distress syndrome (ARDS) and cardiac injury including fatal outcomes (9, 10).

This study was carried out to review the epidemiology of SARS-CoV-2, its host and reservoir, pathogenesis, transmission, clinical manifestation and potential treatment options for the infection.

Materials and Methods

Strategies Used in Searching for Literatures

Literature search for the review was performed in "Science direct", "Google scholar", "PubMed" and also in "MDPI", THE LANCET, "Bioxriv", "JAMA" and "NATURE" journals using the search terms; COVID-19, SARS-CoV-2 and Coronavirus to find articles published before April 13, 2020. Also, some published articles by the WHO and Center for disease prevention and control were included in the analysis. Studies were excluded if data was old and were not pertinent to the aim of the study.

Identification of Relevant Studies

Identification of studies meeting the inclusion criteria was done by two review authors, who screened the titles and abstracts of all retrieved articles. After the selected articles were read, a conclusive decision was made for each study. The inclusion criteria include studies based on experimental data, studies discussing either clinical manifestation, treatment options of SARS-CoV-2 or both, studies based on transmission and host reservoir of SARS-CoV-2 and studies containing information on epidemiology, pathogenesis and symptoms of SARS-CoV-2

A total of 56 articles were screened based on the inclusion criteria and 43 studies were selected and used for the review.

Extraction of Data from Selected Studies

Data was extracted from all selected articles independently by all four reviewers based on the main research objectives; epidemiology, host and reservoir, pathogenesis, transmission, clinical manifestation and potential treatment options for COVID-19.

All findings and statements regarding the outbreak in this study are based on published information as listed in references.

Results and Discussion

Epidemiology

Early cases of COVID-19 were found to have contact history with the original seafood market, however, human-to-human transmission has been identified as disease progresses (11). The first four cases reported, all linked to the Huanan (Southern China) seafood

wholesale market, were identified by local hospitals using surveillance mechanism for "pneumonia of unknown etiology" on December 29, 2019 (12). Laboratory-confirmed 2019-nCoV (COVID-19) cases were identified in 41 admitted hospital patients in Wuhan, China as at January 2, 2020. Most of these patients were reported to have had recent exposure to the Huanan seafood wholesale market, while, half of these patients were reported to have underlying diseases such as diabetes, hypertension and cardiovascular diseases (9).

On January 7, 2020, a novel member of enveloped RNA coronavirus was identified in samples of bronchoalveolar lavage fluid from patients in Wuhan and subsequently confirmed as the cause of COVID - 19 by the Chinese center for disease control and prevention (China CDC) (11). Chinese researchers also shared the full genetic sequence of the novel virus through the national institute of health GenBank database (NIHGD) (13) and the global initiation on sharing all influenza data (GISAID) (14).

The spread of this disease from China to other countries have been rapid with 210 countries and territories having confirmed cases. The global count of confirmed cases as of April 17, 2020, 08:56 (GMT) is 2,190,303 with 1, 489,604 active cases and 147, 027 deaths

Hosts and Reservoir

Bats are natural hosts for a large variety of zoonotic viruses with 47 different virus families detected from bat fecal samples in a recent study (15). Generally, it has been thought that Severe Acute Respiratory Syndrome-related coronavirus (SARSr-CoV) -which is mainly found in bats-could cause future disease outbreaks (16, 17). Benvenuto and his colleagues found that Bat SARS-like coronavirus was homologous and genetically more similar to the novel coronavirus (2019-nCoV) in comparison all other genomic sequences including the SARS and MERS coronaviruses represented in the phylogenetic tree (18).

Analysis of the amino acid sequence of the seven conserved replicase domains in Open Reading Frame (ORF) 1ab used for CoV species classification showed 94.4% similarity between the 2019-nCoV and SARS-CoV. Thus, suggesting that both viruses belonged to same species, SARSr-CoV. Zhou and his colleagues showed that 2019-nCoV genome was highly similar to Bat coronavirus, BaTCoV-RATG13 which was previously detected in *Rhinolophus affinis* from Yuanan province, with 96.2% genome sequence identity. The study showed that RATG13 is the closest relative to 2019-nCoV and they form distinct lineage from other SARSr-CoVs (11).

However, coronaviruses which are phylogenetically related to SARS-CoV-2 have been detected in Pangolins (19). High-throughput sequencing of RNA gotten from samples of 18 malayan pangolins (*Manis javanica*) obtained during anti-smuggling operations performed by Guangxi customs revealed the presence of coronaviruses that fall into the SARS-CoV-2 lineage with similar genomic organization (20). In a study, SARS-CoV-2 exhibits very high sequence similarity to the Guangdong pangolin coronaviruses in the receptor binding domain (RBD; 97.4% amino acid similarity). The Guangdong pangolin coronavirus and SARS-CoV possess identical amino acids at the five critical residues of the RBD, whereas RaTG13 only shares one amino acid with SARS-CoV-2 having only 89.2% similarity (20).

Besides the SARS-CoV-2, SARS and MERS have caused serious outbreaks in humans leading to thousands of deaths in the last two decades (21, 22). All three coronaviruses have been shown to be of bat origin, SARS and MERS seemed to use different intermediate host (16, 23). For example, masked palm civet and dromedary camels are the intermediate hosts for SARS CoV (24) and MERS-CoV (25) respectively. Scientists had thought that bat coronaviruses were not generally capable of infecting humans. This observation is consistent with the fact that ACE2 sequence similarity is higher between humans and pangolins (84.8%) than those between humans and bats (80.8%-81.4%; *Rhinolophus* sp.).

The repeated occurrence of infections with SARS-CoV-2 related coronaviruses in Guangxi and Guangdong provinces suggests that this animal may play an important role in the community ecology of coronaviruses (20). However, the role of pangolin as intermediate host has not been proven.

Pathogenesis

Coronaviruses have different proteins that contribute to its pathogenesis. One of them is the coronavirus spike protein, which is a type I glycoprotein that forms peplomers on the virus. Coronaviruses attach specifically to cellular receptors via the spike protein. The attachment leads to a conformational change of the viral spike protein, and this facilitates fusion of the viral and cellular membranes. The spike protein therefore ensures entry of the virus, cell-to-cell spread of the virus, and it also determines tissue tropism. Coronavirus entry in general, is not said to be pH dependent. The host range of coronaviruses is very low, as their ability to replicate in a host depends on their ability to interact with its receptors (2).

Another protein responsible for its pathogenesis is the Hemagglutinin-esterase protein, which is peculiar to betacoronaviruses (4). The Hemagglutinin-esterase

protein has two domains, a catalytic (esterase) domain and another one that binds to sialic acid-containing receptors. The binding activity helps in the spread of the virus from cell to cell. The acetyl-esterase activity becomes important in places like the respiratory tract where it may need to pass through mucus. It also facilitates S (spike) protein-mediated cell entry of the virus (2, 4).

The membrane protein is important in viral assembly and virus-host interaction. The nucleocapsid is a structural protein that is involved in transcription and pathogenesis. Mutation of structural proteins could be responsible for the higher ability to infect and enhanced pathogenicity that the bat-like SARS coronavirus (18).

Transmission

Being a respiratory virus, human-to-human transmission is primarily through respiratory droplets from coughs and sneezes of symptomatic people within a range of 1.8 meters (6ft) (26). Human-to-human transmission has been confirmed during the SARS-CoV-2 pandemic (27). The SARS-CoV-2 have been found as aerosols floating in air and can cause infection in healthy people (28), however, RNA samples of SARS-CoV-2 have been detected in faecal samples of 2-10% confirmed patients (29).

The incubation period of the virus, which is the time between exposure of the virus (becoming infected) and symptom onset, is on average of 5-6 days, although it can take up to 14 days (30). During this period, also known as "pre-symptomatic" period, some people can be contagious. Pre-symptomatic transmission has been documented through contact tracing and enhanced investigation of clusters of confirmed cases (30, 31).

Clinical Manifestation

Symptoms such as fever, cough, myalgia or fatigue, pneumonia and complicated dyspnea have been reported as the most common symptoms, while, headache, diarrhea, hemoptysis, runny nose and phlegm-producing cough are less commonly reported symptoms (9, 10). Patients with severe cases experiences progressive respiratory failure as a result of alveolar damage whereas, patients with mild symptoms have been reported to recover after 1 week (12).

SARS-CoV-2 has been detected in upper and lower respiratory tract, in fecal samples and in blood samples. Laboratory diagnosis is based on a positive reverse transcriptase polymerase chain reaction (RT-PCR) test (32).

Radiologic assessments include chest radiography or computed tomography. According to the data

compiled by Guan and his colleagues, glass-ground opacity was the most common radiologic finding when chest computed tomography (CT) was carried out. No radiographic or CT abnormality was found in 157 of 877 patients (17.9%) for noncritical cases, and in 5 of 173 patients (2.9%) for critical cases. The imaging patterns found on chest CT performed on the case patients were majorly ground-glass opacity (56.4%) and bilateral patchy shadowing (51.8%). Other imaging patterns included local patchy shadowing and intestinal abnormalities. Also, lymphocytopenia was found 83.2% of the patients, thrombocytopenia in 36.2% and leukopenia in 33.7% (24). There is however, a reported case of acute necrotizing hemorrhagic encephalopathy associated with COVID-19 (33).

Potential Therapeutic Medications for the Treatment Covid-19

At present, there are no antiviral drugs or vaccines approved to cure or prevent infection by SARS-CoV-2. Owing to this, the best measures to control human coronaviruses remain a strong public health surveillance system and also rapid diagnostic testing and quarantine when necessary. Several studies demonstrate several drugs and the ameliorating effects they proffer, there is no putative prophylactic drug or vaccine proven to prevent infection or cure infection.

Toxilizumab and Siltuximab

In a study described by Tao and his colleagues (33), most patients with COVID-19 demonstrated higher circulating levels of interleukin-6 (IL-6) after diagnosis. Its mechanism observed to be shared with other cytokine mediated lung injury perpetrated by infectious agents. The use of the IL-6 inhibitors (monoclonal antibodies), siltuximab and tocilizumab which targets both IL-6 and IL-6 receptors may alleviate cytokine-storm related symptoms of COVID-19 cases (34) as these have been used to treat cytokine release syndrome following CAR-gaT therapy.

Thalidomide

In similar case, in Wenzhou city, China, a 45-year-old woman with COVID-19 was treated with thalidomide with low dosage glucocorticoid. In previous outbreaks such as the SARS and MERS corona virus outbreak, high dosage of glucocorticoid was used to suppress cytokine storms. However, it was associated with adverse side effects such as osteoporosis, secondary bacterial infection amongst others. But in low dosage, coupled with thalidomide, pulmonary effusion symptoms and elevated inflammatory cytokines were significantly reduced. In addition, its efficacy is attributed to its ability to activate T cell receptors and

T cells to enhance immune functions, thus ameliorating organ injury by impeding cytokine storms as well as improving the immune system's potential to fight secondary bacterial infection. It also possesses sedative and antiemetic activities that calms anxious patient, thus reducing oxygen consumption, improving digestive symptoms such as vomiting and promotes relief of lung exudation possibly by impeding the growth of new blood vessels (35).

Oseltamivir and abidolhydrochloride, methylprednisolone, moxifloxacin

Other drugs have shown immense potential at ameliorating COVID-19 related symptoms as seen in Wuhan, China, a couple with COVID-19 were treated with methylprednisolone 40mg (once), human gamma globulin 10g changed later on to 5g. Also, drugs used to treat atypical pathogens such as moxifloxacin for mycoplasma and chlamydia, oseltamivir and abidolhydrochloride for influenza virus and a Chinese patent medicine Tanreqing was administered for adjunctive therapy. The patients showed normal condition after being re-examined for all indication of inflammation. These medications were administered before retrospective studies showed positive results to COVID-19 caused by SARS-CoV-2. Since the patients exhibited no underlying health conditions, recovery could also be attributed to a competent immune system. Nevertheless, these holds promise in alleviating COVID-19 related inflammations (36).

Lopinavir/Ritonavir

In another study, Lim and his colleagues (37) reported lopinavir/ritonavir to be successful in the treatment of 54-year old patient with COVID-19. This was administered day 10 of illness; 2 tablets (lopinavir 200mg, ritonavir 50mg). Clinical results show a decrease in β -coronavirus load with no detectable titre since it was administered. However, speculations pose that improved conditions could be a synergistic effect of natural healing process and the medications or either. Further experiments would be necessary to establish reproducible effects of these medications.

Chloroquine and Hydroxychloroquinone

Chloroquine and hydroxychloroquinone were reported to be effective at preventing escalation of COVID-19 associated pneumonia. Clinical trial showed that chloroquine could block COVID-19 infection at low micromolar (μM) concentrations with half maximal effective concentration of $1.13\mu\text{M}$ and a half cytotoxic concentration greater than $100\mu\text{M}$. In addition, it has also been proven to lung imaging findings, promote a virus negative conversion and shorten the disease course. Its antiviral activity is attributed to its potential to increase endosomal pH

required for virus/cell infusion as well as interfere with glycosylation of cellular receptors of SARS-CoV. In addition to its antiviral properties, it also has anti-inflammatory properties which render it a suitable choice for COVID-19 related pneumonia (38).

Blood Serum

In previous outbreaks known to have ravaged the world, blood plasma from convalescents have been proven to be antidotal in the treatment of Severe Acute Respiratory Syndrome (SARS) and Ebola has shown significant success. This treatment method dates back to the 1918 H1N1 influenza virus where more than 1700 people received blood serum survivors. In 2002-2003, during the SARS outbreak, a study was carried out on 80 persons in Hongkong with convalescent serum. Clinical reports revealed that people treated within two weeks of showing symptoms had a higher chance of recuperating and being discharged from the hospital than those who weren't treated. Likewise blood sera from Ebola survivors have been tested on at least two outbreaks of Ebola in Africa with measurable success (39). Test trials using convalescent serum plasma to treat 13 people critically ill with COVID-19 virus in China, revealed the cessation of circulation of the virus within the patients. Though their conditions continued to deteriorate indicating disease progression too far along for the therapy to be effective (Liang Yu, Zhejiang University School of Medicine in China). In spite of this, this treatment holds great potential to abate spread of infection to forestall immense mortality that could arise from delay in the manufacture of a suitable drug/vaccine.

Remdesivir

Remdesivir is a prodrug of a nucleoside analogue which is metabolized intracellularly to adenosine triphosphate which impedes viral RNA polymerase activity, thus hindering translation of viral genetic material. It has broad spectrum activity against notable viruses which includes filoviruses such as Ebola and corona viruses (Severe Acute respiratory Syndrome Coronavirus (SARS-CoV) and Middle East Respiratory Syndrome Coronavirus (MERS-CoV)). Studies have shown that it possesses some activity against SARS CoV-2 causative agent of COVID-19 illness. More so, remdesivir has shown to prophylactic and therapeutic efficacy in non-clinical models of these coronaviruses (40).

The data of the study showed that gender, region of enrollment, coexisting condition and duration of symptoms before the treatment, was not very significant in measurement of clinical improvement of the 68% of patients that showed improvement with the treatment, 13% including 18% of patients on

invasive ventilation, died after completion of remdesivir treatment.

Although shown to be somewhat effective, the safety of this medication has not yet been ensured as 60% of patients exposed to this treatment reported adverse effects in the follow up (40). The most frequent includes: increased hepatic enzymes, diarrhea, rash, renal impairment and hypotension. In some cases, severe adverse effects were reported. Most common includes: multiple organ-dysfunction syndrome, septic shock, acute kidney injury, and hypotension. These adverse effects were more common in patients receiving invasive ventilation.

Conclusion

Several studies have demonstrated the use of certain drugs to combat infection as some of which target impediment of cytokine-storms which contributes to inflammation (tocilizumab, siltuximab, thalidomide in addition to its sedative, antiemetic and lung exudation relief properties), viral RNA polymerase activity that function in translation of genetic material (remdesivir) and interfere with glycosylation of cellular receptors of SARS-CoV (chloroquinone and hydroxychloroquinone). Phylogenetic studies suggest the novel virus to be closely related to the BaTCoV-2 virus and Guangdong pangolin coronavirus and predicted the SARS-CoV-2 to be of potential harm in the near future. Since bats have been known to be the main reservoir for coronaviruses that have plagued the world, a recurrent surge of another coronavirus of zoonotic origin might occur. Perhaps early identification and characterization of coronaviruses peculiar to bats and pangolins might be a potential solution to the dilemma of drug/vaccine synthesis designed to combat future infections. A major harbinger to the development of novel coronavirus-related infections is the unpredictable wave of genetic mutations supported by natural selection which have been known to confer greater virulence to this group of viruses, bridging the inter-specie barrier between humans and bats. The novel coronavirus SARS-CoV-2, although known to be lethal has been reported to be combatable.
